How much is a public park worth?
An ex ante methodology for impact and
cost-benefit analysis on the example of
Millenáris Széllkapu in Budapest

Abstract. Establishing a public park raises a number of methodological issues. The model worked out by HÉTFA Research Institute is suitable for cost-benefit analysis and ex ante viability test of a public park integrated into urban landscape. The paper presents the model by the example of a planned public park at one of the busiest centers of Budapest, the junction of Margit Boulevard and Millennium Park. Such a comprehensive economic evaluation for public parks has not been made in Hungary. First the mechanism of effects was set up, and by using the hedonic price method the project’s costs and benefits were presented with national and international statistical indicators and benchmarks. The investment, that has been started in 2016 with initial planning and demolition pays for itself by 2019. The results are tested with sensitivity analysis, which has inter alia shown that if we count by the general approach of the project management - costs are expected to increase by 10% and benefits are to reduce by 10% - investment returns for the city and their inhabitants for 2030. Furthermore, without the effect of property appreciation - the investment turns positive by 2061 thanks only to indirect social, economic, environmental benefits. According to our analysis, the park’s development, which relaxes a built-in highly populated urban fabric, has become an economically profitable investment as a result of significant beneficial external effects.

Keywords: public park, cost-benefit analysis, hedonic pricing, impact analysis, urban green infrastructure

Introduction
The importance of creating urban green spaces in urbanism goes back to the beginning 20th century, and the idea first published by Patric Geddes in Cities in Evolution form 1915 [55]. From now the necessity and positive social [98; 63; 31; 81; 106; 12], ecological [102; 52; 115; 86] and economic [104; 31; 72; 88; 73; 135] effects of green spaces are well known. Despite of this fact, at first sight it is more attractive to build in an empty plot in centrally located, urban environment, than establishing a new park for investors and decision-makers. According to our point of view, the main reason for this is the logic of the investor, who counts on the profit of the built-in site and does not have to take into account the costs and benefits of those who are not directly involved in the investment, like inhabitants from neighbourhood or users of the surrounded public places. Encouraging investments that are useful for society, therefore, are regulatory responsibility.

However several international case study exist for assessing effects socio-environmental and economic impacts and a preliminary cost-benefit analysis of investments [62; 117; 12] also several are specialized for parks and green surfaces in urban landscape for example in Tucson (USA) [98], in Joensuu (Finland) [140] in Boston (USA) [134], in Zhuhai (China) [30], in Hongkong (China) [73], in Taiwan [127], in Aalborg (Denmark) [112], in Hungary only few studies deal with the value of green spaces [135; 84]. May be that is the reason for lack of interest from regulatory bodies in Hungary. Taken into account the former mentioned studies, several different aspects exist, but such a complex research was not found during the literature review. The developed new framework of impact and cost-benefit analyses takes into account all aspects of the investment. The methodology can be applied to other domestic and international examples, taking into account specificities, like climate driven benchmarks.

The methodology sets the business as usual (BAU) situation for the basis of the assessment. The set-up mechanism of impacts can generally be used for any public park in any urban landscape, however, severity of the impacts may vary considerably. In the presented example, all effects were evaluated, with one the limitation: not all of them were quantifiable. Some were characterized quantitatively, while others were characterized qualitatively. Quantification was carried out along the hedonic method. A conservative approach was applied: usually the arithmetic average of the benchmark data or the median value of the large deviations were used, but in the case of uncertainty, we used a negative impact with a professional estimate. The effects of abandoned quantification are small, but the result is more positive, so their omission also strengthened our conservative
estimation. We controlled the dependence of the input data through sensitivity analysis.

The methodology was used in the preliminary cost-benefit analysis of the project of Millenáris Széllkapu, in Budapest, Hungary as an illustration of our results. The applied methodology is new in both domestic and international literature, no such work has been done for the construction of a park so far.

**Methodology**

**Mechanism of impacts**

Several literatures are dealing with the impact analysis of urban parks. Rodenburg et al. [117] have divided their comprehensive indicator system to four main groups: socio-economic (availability, usability, multifunctionality, training, etc.), environmental (regulation, function preservation), quality (aesthetics, delimiting functions), financial (authorities, funding).

From this grouping it is visible that the impact of the parks is multifaceted, with many stakeholders. Urban green surfaces help reduce air pollution by absorbing environmental pollutants, thereby reducing adverse health effects and improving air quality, and maintaining air purity [101; 107; 49]. Increasing biodiversity and creating a connection with the natural environment [52], contributing to strengthening urban sustainability, creating and sustaining urban ecosystems through the reinforcement of the network system for green spaces, creating opportunities for species richness growth [86]. In addition, it is important to emphasize that the tree to be planted has a value that can be expressed in monetary terms besides the ecosystem services [115].

Due to the dense built-up of downtown areas and the large-scale paved surfaces, the temperature modification effect of urban landscape can be observed both in winter and summer, causing a rise in temperature in relation to outlying and non-urbanized areas [136]. This phenomenon of thermal insulation causes an average temperature difference between urban and rural areas of 2.5 °C [2]. Urban green surfaces contribute to the reduction of thermal insulation and thus result in savings in summer cooling energy partly due to evaporation, partly due to shielding [102; 101].

The unfavourable health impact of overheating was well-perceived during the 2003 European hot flash when there was an order of magnitude 40,000 more deaths among older people due to extreme weather conditions [54]. However, by a park, an average drop in temperature can be demonstrated to help mitigate all and degenerative mortality [111; 58]. Parks have beneficial health effects beyond thermal insulation. The probability of depression and anxiety disorder, the likelihood of stress or behavioural disturbances decreases near the parks [31; 91; 92; 108]. Among hospital patients, 10% faster healing and less painful analgesic use can be reached at the park-facing room [9]. The park also contributes to the reduction of average treatment costs [108], reduces the average health costs, the effects depend on the difference between the park and the distance between the parks [61].

A proximity of the parks also contributes to the healthy lifestyle, and measurable health benefits have been demonstrated due to active physical activity [64]. Analyses have highlighted that the use of urban green spaces is therapeutic: the recreational impact of the time spent in a natural environment, as well as the movement, sport and walking [31; 12].

Parks in dense urban landscape have a significant sociocultural and recreational impact. According to a survey in Helsinki, easy access of high-quality parks greatly increased the number of visits and park traffic [106]. In Amsterdam, respondents raised the relaxation, the natural environment, the city outgrowth, and the common times spent with children as the main cause of park use [31].

International studies have shown a positive willingness to pay for parks, which draws attention to the strong influence of parks on surrounding urban landscape and its important role in everyday life [85; 9; 127]. Parks also contribute to increasing the attractiveness of the city, which generates economic benefits [31]. The proximity of urban green spaces has a strong impact on the value of nearby real estate, and the urban spaces and parks that have been developed in a qualitative way have a role to play in price management [40]. There is a negative relationship between the price of the property and the distance from the park: the closer we get to the park, the stronger the enhancing effect on the property value [104]. It also has a positive effect when the apartment looks directly at the park [88; 73; 72,]. In Budapest Takács [135] also demonstrated the influence of parks and urban green spaces on real estate value in domestic conditions.

Based on the above-mentioned literature, we have set up the impacts that can be expected from the establishment of the park and their correlations.

**Approbation of the method**

The methodology can be traced back to five steps according to the following:

1. **Basis of the assessment**: stating position for the comparative assessment of investment
2. **Mechanism of impacts**: Setting up economic, social and environmental impacts and impact mechanism
3. **Evaluation methodology**: Definition of impact assessment and quantification methodologies
4. **Cost-benefit analysis**: Comparison of planned expenditures and expected benefits
5. **Sensitivity analysis**: dependence control of input data (Figure 4).
Development area

Millenáris Széllkapu is located in the immediate vicinity of Széll Kálmán Square in the center of Budapest. Its area is 2.4 ha, similar to Central Park Zoo, Manhattan, New York or Square Louise-Michel at Montmartre in Paris, France. In the neighbouring plot on the Margit Boulevard, the outdated building of the ministry was previously dismantled in the initial steps of the investment in 2016. The park to be built on empty land contains the following functions:

- Surface: park, two catering units, BUBI bicycle storage, green wall lookout.
- Underground: 500 parking spaces, lowering Fény Street, and other equipment. The plans of the park were known to our study – these were input data –, the demolition and site preparation work has begun.

Basis of the assessment

It is easy to compare the expected consequences of the project with the business as usual, (BAU) case. However, if there are several possibilities for utilizing an area, more accurate decision can be made by comparing them.

The BAU case, against which we evaluated the positive and negative impacts, has the following characteristics:

- the demolition of the ministry building and Kis Rókus Street buildings will not be realized (related expenses, such as maintenance, are not considered in the analysis);
- the development of the plant stock will not be realised;
- the area is underutilized, it is functionally empty;
- the underground garage will not be realised;
Fig. 2. The development area and its neighbourhood [authors material]

no new functions are created, no revenue generating activity is foreseen;
there is no appreciation for renewal, affecting the area and surrounding city.

Evaluation methodology

The selection of quantified effects was based on the estimated magnitude of the impact and the uncertainty of its estimation. The effects of which magnitude was negligible or were significant based on the literature were characterized qualitatively. The absence of comparative data could only have been assumed to have an uncertain effect. Since in each case different impacts are being evaluated, it is worth making a survey about the magnitude of the impacts. The survey includes environmental characteristics, people's needs and cultural differences.

There are a number of ways to estimate and quantify the effects of green surfaces. The three most commonly used approaches are travel cost, willingness to pay, and hedonic pricing [98]. In order to quantify the data, we rely primarily on studies using the hedonic method. The method is based on benefits of each object, so it consists of all of their features. For the future park, the expected impact was interpreted as a whole [66].
Different benchmark data were used to quantify impacts from domestic and international literature (methodological description see for example [129; 128]). In present study, data analysis and community benchmarking were conducted based on Stapenhurst [129], which consisted of data collection and literature processing that came from domestic or foreign publications. Functionality was taken into account, where the parks play an equal role in this respect in cities and regions, as the Millenáris Széllkapu park will in Budapest, thus ensuring comparability (this is known as the external validity of comparability). International examples were considered with same size, climatic characteristics, environmental features of the park to be constructed (this is referred to as the internal validity of the comparison).

As benchmarks generally refer to other countries’ estimated impacts at other times, it was important and feasible to create equivalent indicators for the year and location of the survey. Two directions were followed: where the data of the study could be formulated as a proportional parameter, those values were used, where not, Hungarian forint, the common domestic currency, in the value of 2016, was calculated using the appropriate exchange rate and GDP deflator. Since the examination was ex ante and a significant part of the benefits and costs are going to be generated in the future, we discounted the 3.25 % interest of the Premium Hungarian State Bond (2016. 11. 25.).

In our example, the effects were divided into two groups: quantifiable and non-quantifiable. Although it was considered important to quantify the impact of the park on the quality of life due to its significant impact, it was nevertheless considered to be an endogenous effect built into a real estate property. Thus, to avoid duplication of the same effects, quantification was not done separately. The quantifiable impacts include the following benchmark-based estimate (Table 1).

**TABLE 1**

Indicators and benchmarks used to the calculation of ex ante assessment of Millenáris Széllkapu project [authors material]
ENVIRONMENTAL SAVINGS: the role of trees in reducing air pollution, the parking benefits of parking and savings from the PM10 mitigation. The characterization of non-quantifiable effects is excluded in our study.

Among the calculated effects (assessment of properties, heating and energy consumption, health effects, tree value, environmental savings) several indicators were identified according to literature review to describe the social effects of the planned development. Three types of indicators were included:

- Once occurred income: Calculated once, at the end of the project, e.g. real estate appreciation.
- Current income: Occur every year in the same amount, e.g. reduction of energy consumption, health expenditures, CO2 and dust control savings.
- Continuously growing income: The planted trees are growing every year, so the effects of ecosystem services are also growing. Calculated at CO2 absorption and tree value.

The basis of the projection

The spatial position of the effects is significantly reduced away from the park. This decreasing effect is true for both real estates and people living there. In present study, surrounding properties and thus the people were divided to different categories: (1) with direct look to the park, (2) who live range of 60 meters, (3) 100 meters or (4) 300-400 meters (5) further catchment area of the park. Apart from a few factors, only the most directly were concerned (1) and (1+2) because of the cautiousness of the estimation results.

Real estate appreciation

A number of studies have confirmed the positive impact of urban spaces, parks and green spaces on real estate. The most important influencing factor is distance [104; 87; 40; 73; 135; 84], the view [72; 88; 73], the nature and conservation of the green surface [89], the green space ratio [105], the increase in park size [112], the street image and public security [87].

We have found empirical results for real estate appreciation between 1.9 and 2.9 %, but also between 10 and 16.88 %. In the calculations, extreme cases were ignored. As a result, a median value was chosen that was compared to local trends – in our case from Budapest [135].

Heat island effect and energy consumption

According to the mentioned studies the following effects can be named. In the development of thermal insulation, low vegetation, better heat storage capacity of urban building blocks [70; 32], urban spaces, waste heat emission – building heat and heat of buildings and vehicles [58; 32; 77; 100; 110] and the proliferating nature of cities play significant role. The local microclimate [123] influences the development of energy consumption [2] and human health [11]. Higher temperatures have more health risks [13; 77; 132; 146; 26]. To reduce this, trees and green infrastructure elements contribute significantly [144; 30]. The vegetation shadows [7; 60] and has better albedo [1] reducing the temperature even from hundreds of meters [59; 45; 150]. The temperature decrease reduces the risk of death [125; 111], and the health expenditures [11].

The lower temperature caused by shadowing and evaporating trees in parks [100; 53], the winding effect and the increase in surface albedo value plays significant role in the decrease of energy consumption of neighbouring properties decreases [67; 1; 2; 7]. The cooling effect of the environment is nearly 3 °C in the summer [2], which results a noticeable decrease in energy consumption [77]. In contrast, in winter, it has a smaller negative effect, resulting in a cooling effect of less than 1 °C, causing a slight increase in energy consumption [59; 101; 28]. The reason for the lower cooling effect observed in winter is the lower the shading ability [36] and evaporative effect of deciduous trees.

Health effects

The presence of a park encompasses a number of health benefits for the surrounding population and the people who use the park, which has social and monetary economic benefits as well. Many studies have demonstrated the positive correlation between human health and the proximity or use of parks [90; 103; 41; 57; 145; 42; 71; 63; 50; 19; 37].

Air pollution is absorbed by vegetation in the park [107], the proximity of the parks is favourable for social life [41], sports [3; 35; 6; 10; 1; 9; 39; 113]. Their effects are measurable in the prevention of psychological illneses [149; 76; 116] helps to recover from a stressful state [79; 119; 44] and prevent its formation [142; 118]. The proximity of parks also reduces average health spending [108; 61].

Tree value appreciation

The theoretical value of a tree goes beyond the direct price, taking into account the ecosystem services and contributions for the social well-being. The applied method, developed by the Hungarian Tree Care Association [133] expresses the economic value and the positive externals also. The most important aspect to calculate the theoretical value is the viability and the condition. In Hungary the evaluation method is based on the Radó-method [115], developed further by the Hungarian Tree Care Association [133].

Reduction of pollutant

Rehabilitation of a former brownfield site creates a healthier and better urban environment.
In our case, the flow conditions are influenced in the first place. The CO$_2$ concentration can be reduced by up to 16 %, as previously reported by Margit Boulevard [4]. After the demolition of the building the ventilation of the area was solved, the distribution of air pollution concentration was also transformed, resulting in a small improvement in air quality [16].

The UFORE (Urban Forest Effects) model [143], used for USA determination, estimates a $\$ 20.3 / tC unit, which includes the marginal social value of carbon dioxide emissions [51]. For other air pollutants it has an accepted market value for social impacts: [NO$_2$: $\$ 6752 / t, PM$_{10}$: $\$ 4508 / t, SO$_2$: $\$ 1653 / t, CO: $\$ 959 / t [105]. The trees in the park have a growing carbon capture and absorption capacity [114; 8; 93] and the dust binding effects [98]. The underground garage also contributes to the reduction of environmental burden, cars are warmed up, which means nearly 50 % less emissions than the cold start [80; 97; 65]. In addition, the surface parking time reduction is reduced, leading to further emission reductions [65].

Further impacts

The following effects were not used in our estimation, although their qualitative evaluation projected positive effects. However, these effects have been incorporated into the model quantitatively:

- Sociocultural relations [14; 147; 138; 78; 5; 38; 24; 148; 130; 74; 91; 137].
- Impact on quality of life [15; 79; 119; 44; 141; 41; 75; 27; 126; 82; 83; 116; 25].
- New opportunities for space use.
- Development of the green space network [21].
- Increase in the value of biological activity (based on the values given in Table 2 of Annex 1 of the ÖTM Decree 9/2007 (IV.3).
- Touristic impact [17; 34; 124; 43; 29; 79].
- Noise and air pollution [68].

Cost-benefit analysis

Following the impact evaluation, we have prepared our table of yearly costs and profits of the investment, discounted by the year of 2016. Certain items, of course, have been generated as a one-off effect (e.g. investment cost or property valuation), while others are constantly present during the period under review due to their annual growth. Thus, it was estimated in which year the value of the projected investment will turn into positive, and how many years will it return to society? It is important to see that the return is just the same for the investor with the return, because the investor is the state itself, which is represents the whole society. A market investor would not have a significant part of the benefits of the investment, so without investing in the state, such an investment would probably never be returned to the investor.

Sensitivity analysis

The impact assessment provides a preliminary estimate and relies on comparative data and benchmarks derived from studies. Therefore, there is a risk of mistake. In such cases, it is common practice to determine the parameters whose erroneous estimation may have the greatest impact on the outcome of the impact assessment. This sensitivity analysis therefore basically serves to...
determine the validity of the estimate and its possible estimation error. It is important to see that sensitivity is two-way. Reality may differ from the estimated value both down and up, but obviously, for a community decision, the higher the risk is the overestimated benefits and underestimated costs. As we have shown above, we have consistently striven for a conservative estimation.

Depending on the types of effects or the risks involved, there are many possibilities for calibrating the sensitivity test. When the possible range of interpretations of some of the known parameters can be used, they can also be used for sensitivity analysis, but we have chosen a simpler approach in our case study: in three steps, we examined whether the difference between ± 10 % ± 20 % and ± 30 % of each parameter would influence the results. The most influencing effects were tested and presented separately (Figure 4).

Results

Cost-benefit analysis

The project of Millenáris Széllkapu, the new park in the centre of Budapest, Hungary, turns to positive to 2024. The incomes that occur once are 16.54 billion HUF (real estate appreciation). The incomes which occur in a annual savings are calculated. For household expenditure. Altogether 25 million HUF for voluntary health care, 4.85 million HUF for state health care, 808,000 HUF for household expenditure. Altogether 25 million HUF savings annual is calculated.

The calculated real estate appreciation is 16,535 HUF annually. The positive to 2024 (±10 %). The real estate appreciation is not included in the cost-benefit analyses, the return delayed to 2062. With the increase of construction costs (return is calculated for 2032) and change led to remarkable effects at real estate appreciation (return is calculated for 2033). All other parameters were unaffected. The reduction of range of real estate appreciation increased the return to/for 2028. The moderate level of real estate appreciation (3 %, instead of calculated 5.9 %) resulted a return for 2042. If the real estate appreciation is not included in the cost-benefit analyses, the return delayed to 2062. With the decrease of all income value by 10 %, the prognosis return is 2019. If we calculate the increase of expenditures and decrease of all income in the same time the return is expected to 2019 (±10 %) and 2025 (±20 %).

Environmental savings: The price of carbon dioxide per tonne is relatively low, the tree absorption (163.08 HUF in the first year) and saving with parking (26.54 HUF in the first year) has low return. However, after 20 years a planted trees absorb the yearly CO₂ production of 6 people (calculated with 332 kg/capita/year by Radó, 2001). More significant is the saving from dust control. Altogether 23.5 million HUF savings annual is calculated.

The results of the cost-benefit analysis are surprising, because the public return is short, however all benchmarks were calculated in a conservative way (the less ambitious values were chosen to calculate the median of international benchmarks and these were adapted to Hungarian circumstances). For that reason, sensitivity analysis was needed, to see how these results change in different scenarios.

Sensitivity analysis

The sensitivity analysis tested all parameters of our model in three stages (±10 %, ±20 % and ±30 % cost reduction or expenditure growth annual in a pessimistic way). The most significant effect is seen with real estate appreciation, so the influenced area was also reduced in our test.

As a result, 10 % change of our parameters did not cause relevant change in our results and the calculated return remained the same. The 20 % change led to remarkable effects at real estate appreciation (return is calculated for 2032) and increase of construction costs (return is calculated for 2033). All other parameters were unaffected. The reduction of range of real estate appreciation increased the return to/for 2028. The moderate level of real estate appreciation (3 %, instead of calculated 5.9 %) resulted a return for 2042. If the real estate appreciation is not included in the cost-benefit analyses, the return delayed to 2062. With the decrease of all income value by 10 %, the prognosis return is 2019. If we calculate the increase of expenditures and decrease of all income in the same time the return is expected to 2019 (±10 %) and 2025 (±20 %).

Discussion

The above described model is based on the idea, that not establishing a public park results more risk for the society, because of the underestimated revenues. According to this all advantages of a public park mentioned in the literature were collected and the expectable revenues were calculated in all possible cases. Some advantageous but hardly predictable effects, like benefits of tourism were not considered. Calculation were based on the values mentioned in literature in all case. The benchmarks were adapted to Hungarian circumstances, were calculated in a pessimistic way.
(lower than median/average values, according to experts’ estimations).

As it is an ex ante study some information were not available, however the permission plans were already finished. For example, precise parameters of trees were unknown, so we calculated with the planned 250 species, from the best quality of 4-year old nursery product. Older trees were not used in the calculation, however in a park in the centre it would be also reasonable, it would also have a positive impact to our results. In addition to the trees, the value of the shrub stocks or the uniformity of avenue trees can also be expressed in cash, but this was also avoided in our conservative calculations.

In case of BAU costs of maintenance and the positive airing effects of demolishing works were neglected. The site remediation was only included in the calculation of costs, the property value increase after the remediation was also neglected.

Some questions were also faced in connection with the existing park (Millenáris Park) directly next to the investment plot. According to our estimations this does not influence our results, because it has a different function, it is an open space for different events, not a park for recreation. The negative effects of this are printed in the real estate prices. The planned investment will corrugate this effect.

However, the real estate appreciation is the most important influencer in our model, as reflected on in the sensitivity analysis. The effect of the existing park is manifested in heat island effects also – it has a remarkable water surface. In the calculations the benchmark value was reduced according to this. Positive health effects away from the plot were not considered, only residents directly neighbourhood of the park were involved.

Such a calculation is applicable to other planned investments, taking account the circumstances of the site and its neighbourhood. These calculations were made in Hungarian Forint (HUF), however, any other currency is suitable for this.

Considering the limitations of our calculations the results go against expectations. The investment of such a park has several positive effects to the society, those were known, but not priced yet. The results are promising, and it would be worth making more calculations to green surface development in built in areas to convince decision makers investors of the competitiveness of establishing public parks in a high-density urban landscape.

Conclusions

The model and the case study of Millenáris Széllkapu investment is a pioneering work in estimating the effects of public parks. It is well known, that an existing park has several positive effects to the society. Mechanism of this effects was mapped, and an evaluation was carried out. Most of them cannot be estimated because of lack of proper measured data or methodology. In the ex-ante cost-benefit analysis the authors focused on the calculatable ones and estimated the long-term incomes in currency (HUF) to get the benefits of the project. The results were compared to expenditures, calculated ex ante by the project management. To validate our results, sensitivity analysis was also performed.

The results are surprising regarding the returns, furthermore several consequences can be made in connection to establishing public parks. In contrast to investor’s attitude, the advantages of a public establishment are realized in wide range. In the case of a public park, this wide range contains all person and economic society uses the catchment area. The finance of a public park is also different, because public money is invested. Externals cannot be understood in the classic way, because all citizen is a stakeholder of the project. In the case of private park, the spread of revenues is limited. According to our estimations, establishing a public park will pay back, if it is situated in an urban landscape with high density, and high property value. In our example the real estate appreciation had the most remarkable influence. That also means that it is worth establishing a park only for real estate appreciation. In a high-density urban landscape, a park establishment do not mean lost revenue for the investor because it increases the value of the plot and appear in the property prices. Several other examples confirm this, like High Lane in Manhattan (NYC) or the success of Kopaszi gát in Budapest, Hungary. Our ex ante analysis confirms this with calculations, according to the model the investment produces a return to 2019.

It is also surprising that the environmental effects are almost neglectable in estimating the effects of a public park. The extent of air pollution is not influenced by the investment, because the source of the emission stays the same, however the absorption of trees is an important element. Another conclusion that the temperature-balancing effect is remarkable on warmer climate, like in Mediterranean regions. On cooler climate the advantages of shading effect are not so appreciable.

From methodological point of view, we would like to highlight the importance of sensitivity analysis. In the case of ex ante assessments, the identification of predictable effects and the risks of the investment are needed. In parallel with this the calculations based on benchmark values are needed to be prudent, pessimistic and accurate to the local circumstances. These are the key factors of successful assessment.
