Abstract
Small rivers are important in terms of water quantity and quality as these rivers collect and deliver water to medium and large rivers downstream. Due to low water flow and high connectivity to adjacent land, small rivers are highly vulnerable to changes caused by natural and anthropogenic factors. This paper aims to assess the chemical and ecological quality of two small rivers including the Slocene and Age as related to dominant land use cover in the contributing area of these water bodies. The effects of land-use patterns and concentrations of chemical substances TN, NO3--N, NH4+-N, TP and PO4--P in river waters will be determined. The highest concentration of total nitrogen (TN) as measured in the Slocene river was 21 mg L−1 in spring, while the lowest concentration of TN was 0.86 mg L−1 in autumn. The highest concentration of total phosphorus (TP) in the Slocene river was 0.14 mg L−1 in late summer, the lowest was 0.03 mg L−1 in late autumn. Similarly, in the Age river, the highest concentration of TN was 4.90 mg L−1 in spring, while TN the lowest concentration of TN was 0.3 mg L−1 in summer, the lowest was 0.05 mg L−1 in autumn. The highest concentration of TP in the Age river was 0.3 mg L−1 in summer, while the lowest 0.05 mg L−1 in autumn.

Key words: agricultural land, forests, chemical and ecological status, nitrogen, phosphorus.

Introduction
An important component of surface waters is small rivers, the amount of which in Latvia is about 6% of the total number of river streams (Apsīte, 2018). According to the national river classification system, these rivers are up to 100 km in length. Rivers of this type are the most vulnerable and susceptible to changes in environmental conditions and anthropogenic activities. Poorly managed anthropogenic activities near small rivers may deteriorate the quality of water ecosystems. Large inputs of plant nutrients from agricultural land improves water fertility, causing increased growth of algae in both inland and seawaters (Nixon, 1995; Klaviņš & Springe, 2011; Voss et al., 2011). Agriculture alone contributes about 80% of the total diffuse load of nitrogen to the Baltic Sea (HELCOM, 2009; Voss et al., 2011).

The smallest particles of soil are colloids, which define the extent and quality of physico-chemical processes in the soil. Soils with relatively high positively charged colloids exhibit more active processes in the soil until it flows away in runoff processes (Mozner, Andrea, & Csutora, 2012). The following forms of nitrogen and phosphorus are considered as nutrients in waters – nitrogen in inorganic ions (NH4+, NO3-, NO2-) and organic compounds of nitrogen, phosphorus in inorganic ions (PO43-, HPO42-, H2PO4-, polyphosphates) and organic compounds of phosphorus (Klaviņš & Cimdiņš, 2004). In the best case, the plants will use 50% of the total amount of fertilizer applied on the soil, 2–20% will be lost in evaporation processes, 15–25% will interact with the clay particles and last 2–10% will enter surface waters (Savci, 2012).

According to soil characteristics and climatic conditions, relatively high amounts of nitrogen are converted into nitrates due to nitrification processes in the soil. Negatively charged nitrate ions are poorly adsorbed to the soil particles, they remain in the soil solution and are flushed away, for example during heavy rainfalls (Nikodemus et al., 2008). Most soils have a high phosphorus binding capacity, so phosphorus leaching from the soil is low in most cases. Up to 90% of the phosphorus is in the form of organic compounds or can be bound to the suspended particles. Phosphorus is transported in dissolved or particulate form. In the form of suspended particles, it is subjected to the water flow and forms the most part of the phosphorus leakage from arable land (Klaviņš & Cimdiņš, 2004; Nikodemus et al., 2008). The influx of pollutants is determined by the turbidity of the substances accumulated in the sediment phase and by the surface runoff from agricultural areas. In autumn, the amount of nutrients is influenced by surface runoff and decomposition of organic matter in the body of water itself (Klaviņš & Cimdiņš, 2004).

Leaching of nitrates and phosphates is an endless process, the second most important cause of diffuse pollution is leaching of organic matter from forest areas which is intensified by cutting down and draining forested areas (Latvijas Vides, geoloģijas..., 2009). Small discharges from manure storage and dairies, dry toilets, silos and septic tanks are also considered as diffuse pollution (Latvijas Vides, geoloģijas..., 2015a).

The chemical contamination of waters with nutrients are characterized by the presence of nitrogen compounds such as total nitrogen (TN), nitrate-nitrogen (NO3−-N), and ammonium nitrogen (NH4+-N), and presence of phosphorus compounds such as total phosphorus (TP) and orthophosphate phosphorus (PO43−-P) (Klaviņš & Cimdiņš, 2004;...
Havlin *et al.*, 2005). In clean waters, TN varies from 0.1 to 0.5 mg L⁻¹, concentrations above 1 mg L⁻¹ indicate anthropogenic pollution. TN is also used as an indicator of the degree of eutrophication in the seas (Nixon, 1995; Klavins & Cimdzins, 2004; Klavins & Springė, 2011). Total phosphorus is a good indicator of the anthropogenic impact on water quality (Nixon, 1995; Klavins & Cimdzins, 2004). For low-impact waters, the concentration of TP is less than 0.05 mg L⁻¹. TP is also used as an indicator of the degree of eutrophication in lakes (Nixon, 1995; Klavins & Cimdzins, 2004; Klavins & Spriņģe, 2011).

The main objective of this paper is to assess the chemical and ecological quality of two small rivers located in different regions in Latvia with specific hydrological conditions and land use.

**Materials and Methods**

The selected rivers of Slocene and Age are located in different parts of Latvia, representing regions with similar climate, but different meteorological conditions, soil texture and farming intensity. All Latvian rivers are divided into six types by its length, river basin area and flow rate (Cabinet of Ministers, 2004).

The Slocene River is a moderate type ritral river (Latvijas Vides, ģeoloģijas..., 2015a) located in the northwestern part of Latvia. The soil texture within the river basin mainly is sandy loam (Nikodemus *et al.*, 2008). The farming in this catchment is moderately intensive, 82.3 km² of the total river basin area is agricultural land (European Environment Agency, 2018). According to Latvijas Vides, ģeoloģijas..., 2005 the average TN concentration in this river is 3.5–4.5 mg L⁻¹ which is rated as being high, but TP is >0.18 mg L⁻¹ rated as very high.

The Age River is a moderate type ritral river (Latvijas Vides, ģeoloģijas..., 2015b) situated in the northeastern part of Latvia. The soil texture within river basin mainly is sandy clay (Nikodemus *et al.*, 2008). The farming in this river basin is moderately intensive, 95.5 km² of the total river basin area is agricultural land (European Environment Agency, 2018). The average TN concentration is 1.5–2.5 mg L⁻¹ rated as moderate, but TP is <0.06 mg L⁻¹ rated as very low (Latvijas Vides, ģeoloģijas..., 2005). Main characteristics of the selected rivers are compiled in Table 1.

Both rivers are moderately deep with a stream speed of >0.2 m s⁻¹. The bottom substrate is formed from sand, gravel and stones (Latvijas Vides, ģeoloģijas..., 2015a, 2015b).

The main diffuse pollution sources are agriculture and background pollution from forests. The Corine Land Cover 2018 database (European Environment Agency, 2018) information is used to obtain the basic data for evaluation. According to the information summarized, a specific area of agricultural land and forested land in each water body is expressed as a parameter relative to the total area of the water body.

The concentrations of TN, NO₃⁻N, NH₄⁺-N, TP and PO₄³⁻-P in river waters were analyzed. Samples in the river were taken between 2007 and 2018 with various intervals. Water samples were filled into 1.5 L pure plastic bottles and delivered to the Latvia Environment, Geology and Meteorology Centre laboratory for analysis. TN concentrations were determined by the LVS EN 12260:2004 method.
Nitrogen and phosphorus compounds were determined by different methods. NO$_3^-$-N concentrations were determined by the LVS EN ISO 13395:2004 method (Latvian Standard, 2004a). NH$_4^+$-N concentrations were determined by the LVS EN ISO 11732:2005 method (Latvian Standard, 2005a). TP and PO$_4^{2-}$-P concentrations were determined by the LVS EN ISO 6878:2005 method (Latvian Standard, 2005b).

To assess the importance of diffuse pollution sources, the basic data on the distribution of agricultural land and forests in each water body was calculated. To compare data statistically, the analysis of one-factor linear regression was conducted. Changes in the concentrations of nitrogen and phosphorus compounds depending on the sampling time are considered significant ($p \leq 0.05$) if the concentrations of leached chemical compounds increase in spring and autumn but decrease in summer and winter.

The assessment of the water quality of the Age and Slocene rivers has been made according to Water Framework Directive 2000/60/EC and the Nitrate Directive 91/676/EEC instructions and threshold values for surface water body water quality assessment, which in Latvia are integrated into CM Regulation No.118 ‘Regulation of quality of surface water and groundwater’.

**Results and Discussion**

Latvia is located in a humid climate zone with mild weather conditions, where rainfalls exceed evaporation and access water drains into watercourses (Jansons et al., 2003). The specific runoff of a river is affected by the amount of rainfall at each location over the given period of time (Randall & Mulla, 2001; Iital, 2005). The annual precipitation rate in the northwestern part of the Venta River basin district is 650–700 mm, but in the northeastern part of the Gauja River basin district is 700–750 mm (Latvijas Vides, ģeoloģijas…, 2015a, 2015b). The maximum amount of precipitation is measured in August, while minimum in February. According to water body specific precipitation rates, the annual runoff in the Slocene River is 220 mm, while in the Age River 280 mm (Latvijas Vides, ģeoloģijas…, 2015a, 2015b). The runoff differences between the selected research sites strongly depend on the amount of precipitation. It has been found that runoff from subsurface drainage is the main nutrient transport route from soil profiles to streams – therefore, for analyzing nutrient concentrations in water, the climatic and hydrological conditions of the research site must be taken into account (Randall & Mulla, 2001; Iital, 2005).

In order to determine which sources of diffuse pollution are significant, there is a need to assess whether the values of the land use characterizing economic activities are not close to the limit values above which the ecological quality of water bodies is deteriorating. In the current intensity of economic activity in Latvia, the most significant diffuse pollution loads are characterized by the proportion of agricultural land and forests in the water body (Latvijas Vides, ģeoloģijas…, 2015a).

The total catchment area of the Slocene River basin is 241.8 km$^2$; main land-use types are artificial surfaces, agricultural areas, forests, wetlands and water bodies (Figure 1). Agricultural lands of the Slocene River consists of non-irrigated arable land, fruit trees and berry plantations, pastures, complex cultivation patterns and land principally used in agriculture, which is about 34.5% of the total catchment area. Near the Slocene River broad-leaved, coniferous, mixed forests, natural grasslands and transitional woodland shrubs are growing, which is about 48.8%
of the total catchment area (European Environment Agency, 2018).

The total catchment area of the Age River basin is 202.03 km², main land-use types are artificial surfaces, agricultural areas, forests, wetlands and water bodies (Figure 2). Agricultural lands of the Age River consists of non-irrigated arable land, pastures, complex cultivation patterns and land principally used in agriculture, which is about 47.3% of the total catchment area (European Environment Agency, 2018). Total catchment area, agriculture land and forest occupied area of the selected river basins are compiled in Table 3.

According to the methodology for the assessment of ecological status, the water quality in the Slocene river basin is evaluated as good, while in the Age River basin as very poor. In both river basins leaching risks of nutrients are high (Latvijas Vides, ģeoloģijas..., 2005), but a larger share of agricultural land in the Age River basin reflects lower ecological level of the river basin. According to the assessment of ecological status forests in both river basins have a high-quality class. This is due to the relatively large and unmodified forested areas. In the Venta River basin district, 20% of the total forest area is covered with forests, which have been drained to improve forest growth conditions and increase productivity (Latvijas Vides, ģeoloģijas..., 2015a). The same situation applies to the Gauja River basin district, where 60% of the land is covered with forests (Latvijas Vides, ģeoloģijas..., 2015b). The ecological status in both river basins is decreasing by the size of agricultural lands relative to the total

catchment area. Assessment of ecological status for the Slocene and Age rivers is shown in Table 4.

The changes in nutrient concentrations over time correlate with hydrological conditions. In both water bodies, the highest concentrations of nutrients were found in early spring and late autumn. In the Slocene river, the highest concentration of TN was 21 mg L⁻¹ in spring, while the lowest concentration of 0.86 mg L⁻¹ in autumn. The highest concentration of TP in the Slocene River was 0.14 mg L⁻¹ in late summer, but the lowest of 0.03 mg L⁻¹ in late autumn (Figure 3).

Similarly in the Age River, the highest concentration of TN was 4.90 mg L⁻¹ in spring, while the lowest of 0.51 mg L⁻¹ in late autumn. The highest concentration of TP in the Age River was 0.3 mg L⁻¹ in summer, but the lowest 0.05 mg L⁻¹ in autumn (Figure 4). Summary of nutrient concentrations in the selected rivers is shown in Table 5.

A linear regression analysis of TN and TP concentrations as shown in Figure 3 and 4 indicate that over time the concentrations of TN decrease for the Age River and increase for the Slocene River.
In the case of TP concentrations, time trends are opposite, the concentrations increase and decrease for the Age River and Slocene River, respectively. Nutrient concentrations in rivers are characterized by seasonal variability. There is an increase in nutrient concentrations during spring floods and to lesser extents in autumn floods.

The model proposed by the authors is unsuccessful, all except the Age River model TN $p=0.048$ with a level of confidence 95%, is not relevant $p>0.05$. The date and month of analysis do not explain the levels of nutrient concentrations in the rivers. There is lack of information on the amount of precipitation and fertilizer amount in river basin areas, the temperature, etc.

Although the ecological status in the Age River is very poor, the annual mean concentrations of TN in the Age River is above-average values of TN concentrations of 1.5–2.5 mg L$^{-1}$ (Latvijas Vides, ģeoloģijas..., 2005). Depending on the soil type, the Age River basin agricultural land is less fertilized, 30.5 kg of nitrogen and 1.98 kg of phosphorus per 1 hectare of land are released in the Gauja River basin per year (Latvijas Vides, ģeoloģijas..., 2015b). According to Latvian Environment, Geology and Meteorology Centre, 34.8 kg of nitrogen and 2.69 kg of phosphorus per 1 hectare of land are released in the Venta River basin per year (Latvijas Vides, ģeoloģijas..., 2015a). Nitrate-nitrogen (NO$_3$-$N$) threshold level for good water quality according to the EU Commission (1991) is 11.3 mg L$^{-1}$ which is equivalent to 50 mg L$^{-1}$ nitrates (NO$_3$-). This threshold value is not exceeded in the Slocene and Age Rivers with one exception in the Slocene River.

**Conclusions**

1. The ecological and chemical status of the Slocene and Age rivers depend on number of factors including soil type, climatic conditions, land use types, and anthropogenic activities.
2. The highest concentrations of nutrients have been measured during the spring period. This indicates that snow accumulation during the winter season is rather high in these waterbodies, and snow melt during the spring may cause increased nutrient losses from diffuse sources.
3. There is a need to implement edge-of-field practices such as sedimentation ponds, constructed wetlands, bottom dams, meandering, controlled drainage, and two-stage ditches in the Slocene and Age waterbodies in order to reduce nutrient losses from diffuse sources.
